AIM:	Program on Open Addressing Hashing
Program	
PROBLEM STATEMENT:	Implement Quadratic Probing technique for collision resolution in an open addressing hash table
THEORY:	<p>Hashing:</p> <p>Hashing is a technique used for storing and retrieving information as quickly as possible. It is used to perform optimal searches and is useful in implementing symbol tables.</p> <hr/>  <p>Components of Hashing:</p> <ol style="list-style-type: none"> 1. Hash Table 2. Hash Functions 3. Collisions 4. Collision Resolution Techniques

Hash Table:

Hash table is a generalization of array. With an array, we store the element whose key is k at a position k of the array. That means, given a key k , we find the element whose key is k by just looking in the k th position of the array. This is called direct addressing. Hash table or hash map is a data structure that stores the keys and their associated values, and hash table uses a hash function to map keys to their associated values. The general convention is that we use a hash table when the number of keys actually stored is small relative to the number of possible keys.

Hash Function:

Hash table or hash map is a data structure that stores the keys and their associated values, and hash table uses a hash function to map keys to their associated values. The general convention is that we use a hash table when the number of keys actually stored is small relative to the number of possible keys.

Characteristics of Good Hash Functions:

1. Minimize collision
2. Be **easy** and quick to **compute**
3. **Distribute** key values **evenly** in the hash table
4. Use **all** the **information** provided in the key
5. Have a **high load factor** for a given set of keys

Collisions:

Hash functions are used to map each key to a different address space, but practically it is not possible to create such a hash function and the problem is called collision. Collision is the condition where two records are stored in the same location.

Collision Resolution Techniques:

The process of finding an alternate location is called collision resolution. There are a number of collision resolution techniques, and the most popular are separate chaining and open addressing.

Open Addressing:

It is an Array-based implementation of hash table which uses 3 types of probing techniques to minimize collisions:

Quadratic Probing:

The interval between probes increases proportionally to the hash value (the interval thus increasing linearly, and the indices are described by a quadratic function). The problem of **Primary Clustering** can be eliminated if we use the quadratic probing method.

Hashing Function is given by: $h(k,i) = (h'(k) + c_1*i + c_2*i*i) \% m$
where $h'(k)$ is an auxiliary hash function, C_1 and C_2 are positive auxiliary constants, and $i = 0, 1, 2, \dots, m-1$. The initial position probed is $T[h'(k)]$; later positions probed are offset by amounts that depend in a quadratic manner on the probe number i . This method works much better than linear probing, but to make full use of the has table, the values of c_1, c_2 & m are constrained.

6	76

Insert 73 and 101

Disadvantages:

Even though clustering is avoided by quadratic probing, still there are chances of clustering. Clustering is caused by multiple search keys mapped to the same hash key. Thus, the probing sequence for such search keys is prolonged by repeated conflicts along the probing sequence. Both linear and quadratic probing use a probing sequence that is independent of the search key.

ALGORITHM:

1. Create OQHash class with int[] hashtable & int size members
2. Initialize constructor and set size, c1 & c2
3. Create methods for hashing

CreateHash Method:

1. for i=0 to i<size:
2. set hashtable[i] to -1
3. end for loop

quadraticProbe Method:

1. initialize I to 0 & count=0
2. initialize index = key%size
3. while hashtable[index] is not equal to -1:
4. index = (index+(c1*i)+(c2*i*i))%size
5. if hashtable[index] is not equal to -1:
6. increment I & count
7. end if
8. if count is more than size-1:
9. return -1
10. end if
11. end while loop
12. return index

HashInsert Method:

1. index = **quadraticProbe(key)**
2. if index is not equal -1:
3. set hashtable[index] = key
4. else print element not inserted
5. end if

HashDisplay Method:

1. for i=0 to i<size:
2. print I & hashtable[i] → prints index and key
3. end for loop

PS D:\Data Structures\Exp10>

CONCLUSION:

In this experiment, we learned how to implement a hash table using arrays and how to implement quadratic probing using constants to minimize collisions occurring while mapping keys.
